LIZARDS AND SNAKES (LEPIDOSAURIA, SQUAMATA) FROM THE LATE QUATERNARY OF THE STATE OF CEARÁ IN NORTHEASTERN BRAZIL

ANNIE SCHMALTZ HSIOU, PAULO VICTOR DE OLIVEIRA, CELSO LIRA XIMENES, AND MARIA SOMALIA SALES VIANA

Abstract: We present the first formal report on the squamate assemblage from Parque Nacional de Ubajara. This park contains the most important cave complex in the state of Ceará in northeastern Brazil, called Província Espeleológica de Ubajara. The material comes from the Urso Fossil cave at Pendurado Hill. All previously reported fossil remains found in this cave are tentatively attributed to the Quaternary (late Pleistocene–early Holocene). Probably only Arctotherium brasiliense represents a relictual fossil bear from the late Pleistocene megafauna. The taxa recognized in this paper belong to Tropidurus sp., Ameiva sp., cf. Epicrates, and cf. Crotalus durissus, adding to the knowledge of the Brazilian Quaternary squamate fauna as a whole, and contribute to a major taxonomic refinement of the squamate assemblages from the early Holocene of northeastern Brazil.

INTRODUCTION

The Brazilian Quaternary record of Squamata (i.e., lizards, amphibiaenians, and snakes) has been documented mainly in the southeast and northeast regions, with several taxa correlated to the current Brazilian herpetofauna (Camolez and Zaher, 2010; Hsiou, 2010). Many records, however, have not been formally studied and described (Lund, 1840; Paula-Couto, 1978; Lino et al., 1979; Barroso-Barreto et al., 1982; Guérin, 1991; Guérin et al., 1993; Faure et al., 1999) and their taxonomic and systematic status remains unclear.

Some of the most diverse squamate faunas from the late Pleistocene–Holocene of Brazil were recently studied. The fossils were collected in caves and rock shelters in the states of Bahia (northeastern Brazil), Goiás, Mato Grosso (midwestern Brazil), Minas Gerais, and São Paulo (southeastern Brazil; Camolez and Zaher, 2010). A large number of lizards (Tropiduridae, Leioosauridae, Polychrotidae, Teiidae, and Anguidae), snakes (Boidae, Colubridae, Viperidae, and Elapidae) and amphibiaenians (Amphisbaenidae) were described, and the majority of fossils were attributed to extant neotropical species (Camolez and Zaher, 2010). All fossils were identified based on osteological comparison with extant species. However, there is only a single record of snakes (Viperidae) from the late Pleistocene of southwestern Brazilian Amazonia (Hsiou and Albino, 2011). Beyond these records, some extinct species including two amphibiaenians, Amphisbaena braestrupi and A. laurenti, were reported from the late Pleistocene–Holocene of Lagoa Santa region, Minas Gerais State (Gans and Montero, 1998), as was the extinct teiid lizard Tupinambis uruguaiensis, from the late Pleistocene of the Touro Passo Formation, Rio Grande do Sul State, southern Brazil (Hsiou, 2007).

Recent fieldwork was undertaken at Parque Nacional de Ubajara, where the most important cave complex in the state of Ceará in northeastern Brazil is located, part of a notable karstic system (Oliveira, 2010). Small mammals, such as bats, rodents, and marsupials (Ximenes and Machado, 2004), were among the taxa recorded. Other records include artiodactyls (deer and peccaries), perissodactyls (tapirs), xenarthrans (armadillos), and felines (Ximenes and Machado, 2004; Oliveira, 2010), as well as a single member of the late Pleistocene megafauna, the fossil bear Arctotherium brasiliense (Trajano and Ferrarezi, 1995). Other records are from deposits in tangues (natural depressions formed in granitic rocks that accumulate sediments and fossils), such as undetermined remains of lizards and snakes reported by Paula-Couto (1980) as being recorded from Pleistocene deposits of the Itapipoca region.

Recently, Hsiou et al. (2009) briefly reported on some snake vertebrae from the families ‘Colubridae’ and Viperidae from the late Quaternary in Província Espeleológica de Ubajara. Their report did not contain stratigraphic data (see also Trajano and Ferrarezi, 1995; Ximenes and Machado, 2004) or radiometric (geochronologic) control. Here we describe new material from the early Holocene in the state of Ceará in Brazil based on the most recent
fieldwork done in the Ubajara region, during July 2009, with precise stratigraphic and radiometric control.

**Location and Geological Setting**

The Parque Nacional de Ubajara is located in Ubajara Municipality (Fig. 1), in Ibiapaba Cuesta in the northwestern portion of the state of Ceará (northeastern Brazil), which possesses a notable karst system. The speleological province of the Ubajara region consists of nine limestone hills with fourteen known caves (IBAMA, 2002). The limestone rock cropping out in the region corresponds to the Frecheirinha Formation of the Ubajara Group, Neoproterozoic of the Ubajara Graben (Quadros, 1996; CPRM, 2003). The Ubajara Group has an unconformable contact with the rocks of the Serra Grande Group, Silurian-Devonian of the Parnaíba Basin (Nascimento et al., 1981). Among the limestone hills in the studied area, the Pendurado Hill includes two important fossiliferous caves: Urso Fossil and Pendurado.

All fossil remains are attributed to the Quaternary (late Pleistocene-early Holocene), however, the fossil bear *Arcototherium brasiliense* is probably the only relict in this fauna of the Pleistocene megafauna (Trajano and Ferrarezzi, 1995), found at Urso Fossil cave (03°49'58"S, 40°53'34.4"W). The material studied was found in one room of this cave, called Sala de Entrada. A controlled stratigraphic excavation in this room exposed three layers of sedimentary deposits, and all fossil remains belong to the early Holocene. A geological section provided information about unconsolidated accumulations of allochthonous (biogenic and siliciclastic from outside the cave) and autochthonous (generated inside the cave) material. The stratigraphic layers include sediments from the bottom to top (Fig. 2):

**Layer 1** has a thickness of 0.20 m and is comprised of carbonaceous silt-clay sediments, containing smaller autochthonous fragments of limestone and large, angular fragments of speleothems. In this layer, there are shells of freshwater clams and several carbonized bone fragments. As in layer 2, a sample was collected for thermoluminescence dating; more details can be found in Oliveira et al. (in press). Remains of squamate reptiles and mammals such as Didelphimorphia, Xenarthra, Rodentia, and Artiodactyla were found.

**Layer 2** has a thickness of about 0.35 m and is composed of light gray clay containing autochthonous fragments of limestone (> 2 cm), some small geodes, and fragments of stalactites (approximately 10 cm diameter) and other speleothems, in some cases, showing concentrations of iron oxide. The top of the layer contains a high concentration of two types of undetermined seeds. At the bottom of the layer, some complete shells of freshwater clams and several fragments of shells had accumulated. There are small feces covered by powdered carbonate, but still unconsolidated. Some 20 cm from the top of this level, sediment samples were collected in PVC pipe for thermoluminescence dating, and below that, samples were obtained for recovery of palynomorphs. Gastropods and several fragments of Didelphimorphia, Xenarthra, and Rodentia, were collected.

**Layer 3**, with a 0.15 m thickness, is composed of light yellowish, silty-clay sediments of carbonate-rich composition, containing small autochthonous fragments (0.5–1 cm) of amorphous and angular limestone, and a great amount of recent seeds and fecal matter.

**Material and Methods**

The material studied includes isolated dentaries and vertebrae deposited in the collection of Museu Dom José

*Figure 1. Location map of late Quaternary of Província Espeleológica de Ubajara, Ceará State, Brazil.*
(MDJ), in the State Ceará, Brazil. The material consists of two lizard dentaries (MDJ R-004 and 005) and five vertebrae of snakes (MDJ R-006, 020, 024, 026, and 027). The osteological nomenclature and systematics follow Estes (1983), Presch (1974), Estes et al. (1988), Frost et al. (2001a,b), Nydam and Cifelli (2002), and Nydam et al. (2007) for lizards; and Auffenberg (1963), Hoffstetter and Gasc (1969), Rage (1984), Zaher (1999), and Holman (2000) for snakes.

SYSTEMATIC PALEONTOLOGY

SQUAMATA Opell, 1811
IGUANIA Cope, 1864
TROPIDURIDAE Frost and Etheridge 1989 sensu Frost, Janies, and Titus, 2001a
Tropidurus Wied, 1824
Tropidurus sp.
(Fig. 3)

Material: MDJ R-005, complete right dentary.

Stratigraphic provenance: Parque Nacional de Ubajara, Pendurado Hill, Urso Fossil Cave, Sala da Entrada, layer 1 (TL 8,200 ± 980 years BP), early Holocene.

Description: MDJ R-005 is a complete and delicate right dentary with four mental foramina in labial view. The dentary bears thirteen pleurodont teeth preserved in eighteen tooth positions. The mesial teeth are anteriorly inclined and unicuspid. The distal ones are tricuspid, with two accessory cusps, a mesial and a distal one, smaller than the main central cusp. Under the last two posterior teeth, the subdental shelf of the dentary possesses a notch that extends obliquely until the last teeth (Camolez and Zaher, 2010). The symphysis is small and slightly dorsally oriented. Meckel’s groove is extensively closed, with an anterior opening restricted to an elongate foramen and a posterior notch under the last two distal tooth positions. The posterior process of the dentary is long when compared to the total size of the dentary. In labial view, the dorsal margin of the posterior process of the dentary shows a flattened surface, for the contact with the anterior process of the coronoid.

Discussion: Species of Tropidurus are widely distributed in open areas in the tropical and subtropical regions, from southern Venezuela east through the Guianas to northeastern Brazil, and from there southwest of the Amazonian region to eastern Bolivia, northermost Uruguay, and central Argentina (Etheridge, 1964; Ávila-Pires, 1995; Frost et al., 2001b). There are four species groups formally diagnosed within the genus: T. spinolusus group, the T. borgeti group, the T. semitaeniatus group, and the T.
torquatus group (Frost et al., 2001b). Attribution to the species level of MDJ R-005 was not possible; but the presence of a longitudinal impression on the labial surface of the posterior part of the dentary, which rises posteriorly (slight “erosion” of the alveolar shelf) should be an apomorphy supporting assignment of MDJ R-005 to the “Tropidurus group” (Frost, 1992; Frost et al. 2001b).

SCLEROGLOSSA Estes, de Queiroz and Gauthier, 1988
SCINCOMORPHA Camp, 1923
TEIIOIDEA Estes, de Queiroz and Gauthier, 1988
TEIIDAE Gray, 1827
TEIINAE Presch, 1974
Ameiva Meyer, 1795
Ameiva sp. (Fig. 4)

Material: MDJ R-004, incomplete right dentary.

Stratigraphic provenance: Parque Nacional de Ubajara, Pendurado Hill, Urso Fossil Cave, Sala da Entrada, layer 1 (TL 8,200 ± 980 years BP), early Holocene.

Description: MDJ R-004 is a robust but incomplete right dentary. Its anterior portion is fragmented at the symphysis, and the ventral, lingual and labial portions also are broken. There are three mental foramina in labial view. The dentary rises posteriorly toward its labial and lingual articulations with the coronoid. Lingually, only the anterior portion of the splenial is preserved. Meckel’s groove is restricted to the anterior region of dentary by the development of the subdental shelf showing a straight groove (Brizuela, 2010). There are eleven subpleurodont teeth preserved in sixteen tooth positions, within a sulcus dentalis and with heavy deposits of cementum at tooth bases (Estes et al., 1988; Nydam and Cifelli, 2002). The third mesial tooth preserved is conical and apparently unicuspoid, relatively smaller than the distal ones. The fourth tooth is damaged, but two accessory cusps can be seen, a mesial and distal one, both slightly posteriorly oriented. The fifth, sixth, and seventh are replacement teeth within the replacement pit and show two accessory cusps, both cusps being almost vertical and aligned with one another. The eighth tooth is broken at the base. From the ninth to the eleventh tooth, tooth size and interdental spacing increases (“enlarged posterior teeth: a greater degree of molariformy”, Estes and Williams, 1984). Two accessory cusps are present, as on the fourth preserved tooth.

Discussion: The genus Ameiva displays a wide geographical distribution, occurring in southern Mexico, Central and South America, and in many Caribbean islands, with different species (Ávila-Pires, 1995; Pianka and Vitt, 2003). The genus has been considered a paraphyletic group (Presch, 1974; Reeder et al., 2002; Giugliano et al., 2006, 2007), although some authors defended monophyly (Hower and Hedges, 2003). Among the Ameiva species, the most studied is A. ameiva, commonly found in open habitats, coastal and forests environments, and frequently seen in perianthropic situations (Ávila-Pires, 1995).

Following Camolez and Zaher (2010), the largest size among small Teiidae (such as Cnemidophorus, Kentropis and Crocodilurus) and the dental morphology would allow referral of MDJ R-004 to the species Ameiva ameiva. Nevertheless, no additional osteological materials have been found to support this attribution. Currently, we cannot identify MDJ R-004 to species.

Epicrates Wagler, 1830
cf. Epicrates sp.
(Fig. 5)
Material: MDJ R-020, incomplete midtrunk vertebrae.
Stratigraphic provenance: Parque Nacional de Ubajara, Pendurado Hill, Urso Fossil Cave, Sala da Entrada, layer 1 (TL 8,200 ± 980 years BP), early Holocene.
Description: MDJ R-020 lacks most of the dorsal part of the neural arch. The specimen is small, relatively robust and high, with a short centrum. The vertebra probably is a midtrunk vertebra, given the presence of a well marked and anteroposteriorly developed haemal keel. In general view, the prezygapophyses are slightly inclined dorsally, antero-laterally oriented, and display a short prezygapophyseal process. The articular facets of the prezygapophyses are triangular. There are small lateral foramina. The centrum is triangular, widened anteriorly, and rather narrow. A deep paracotylar depression is present to either side of the cotyle, but foramina are absent there. The paradiapophyses are broken, but were apparently robust and oriented dorsoventrally, surpassing the ventral edge of the cotyle. The haemal keel is well-marked and begins on the ventral edge of the cotyle. The subcentral ridges are weakly marked; the subcentral grooves are shallow, but this is more evident in the middle portion of the centrum, lateral to the haemal keel. There is one pair of subcentral foramina.
Discussion: The endemic Neotropical genus Epicrates is currently recognized as a paraphyletic group in relation to Eunectes, owing to recent studies that found mainland Epicrates in a sister-group relationship with Eunectes (Burbbrink, 2005; Noonan and Chippindale, 2006). The genus contains ten species (Kluge, 1989; McDiarmid et al., 1999) and comprises two monophyletic groups (Kluge, 1989; Passos, 2003; Burbbrink, 2005; Noonan and Chippindale, 2006; Passos and Fernandes, 2008). An insular group distributed in the West Indian islands contains twenty-one taxa (Henderson and Powell, 2007), whereas Epicrates cenchria (Linnaeus) is a continental endemic (McDiarmid et al., 1999; Passos and Fernandes, 2008). Of the previous nine subspecies of E. cenchria, five are now recognized as distinct species E. alvarezi, E. assisi, E. cenchria, E. crassus, and E. maurus based on statistically robust delimitation of species boundaries (Passos and Fernandes, 2008). The taxonomic assignment of the specimen described above is based on the following combination of vertebral characters shared with the genera of extant neotropical boines: robust, short and wide vertebra, low inclination of the articular facet of the prezygapophysis (less than 15°); short prezygapophyseal process, vertebral centrum short, marked precondylar constriction, haemal keel well developed in the midtrunk vertebrae, and presence of subcentral and lateral foramina (Rage, 2001; Lee and Scanlon, 2002; Szyndlar and Rage, 2003; Albino and Carlini, 2008; Hsiou and Albino, 2009, 2010). Within the neotropical boines, the trunk vertebra is similar to samples from individuals of the genera Epicrates and Corallus, differing from Eunectes and Ameiva sp., incomplete right dentary, MDJ R-004: A, labial view; B, lingual view. Scale bar = 10 mm.
Boa in its smaller size (Hsiou and Albino, 2009, 2010). According to Hsiou and Albino (2010), Epicrates and Corallus could be distinguished by the morphology of the anterior lobe on the anterior edge of the zygosphene, but MDJ R-020 lacks most of the neural arch. In Corallus the prezygapophyses are mostly horizontal in anterior view, whereas they are relatively more inclined above the horizontal plane in Epicrates (Hsiou and Albino, 2010). For this reason, we tentatively assigned the trunk vertebrae MDJ R-020 to cf. Epicrates.

CAENOPHIDIA Hoffstetter, 1939  
COLUBROIDA Oppel, 1811  
VIPERIDAE Oppel, 1811  
Crotalus Linnaeus, 1758  
Crotalus durissus Linnaeus, 1758  
cf. Crotalus durissus (Fig. 6)

Material: MDJ R-006, 024, 026 and 027, incomplete trunk vertebrae.

Stratigraphic provenance: Parque Nacional de Ubajara, Pendurado Hill, Urso Fossil Cave, Sala da Entrada, layer 2 (MDJ R-006, TL 8,000 ± 990 years BP) and layer 1 (MDJ R-024, 026, 027, TL 8,200 ± 980 years BP), early Holocene.

Description: The preservation of the vertebrae varies among specimens. MDJ R-006 and 024 lack most part of the neural spine, hypapophysis, right prezygapophysis and parapophyseal process, and both paradiapophyses; MDJ R-026 lacks the hypapophysis and right prezygapophysis and parapophyseal process; MDJ R-027 lacks most of the neural arch, zygosphene, hypapophysis, and left prezygapophysis and paradiapophysis. The zygosphene is thin and shows a concave anterior margin, with small and dorsally angled articular facets. The neural arch is wider than long, is moderately depressed, and bears a deep posterodorsal notch. The neural canal is subtriangular, low and wide. The articular facets of the prezygapophyses are slender, longer than broad, with the main axis rather laterally oriented. A small prezygapophyseal process projects slightly beyond the articular facets of the prezygapophysis. The parapophyses are clearly oriented dorsoventrally as a whole. The diapophysial and parapophyseal surfaces are distinct from each other. The parapophyses are well developed, with a prominent and spherical diapophysis, distinct from a large and concave parapophysis (seen in MDJ R-024). A well-developed and strongly inclined parapophyseal process is spatulated projecting anteriorly, and extends clearly beyond the ventral rim of the cotyle. The postzygapophyses are elongated and inclined dorsolaterally. The zygantra are large and deep, with a small foramen within each side of zygantrum. The neural spine is very well developed, high, and considerably elongated anteroposteriorly, seen in MDJ R-026. The interzygapophyseal constriction is deep and curved. Small lateral foramina are evident on the side walls of the neural arch, more or less positioned at the diapophysial level. The cotyle and condyle are nearly circular, and one pair of small paracotylar foramina is evident; one foramen is located on each side of the cotyle, placed in a shallow depression. The centrum is triangular and bears a very prominent hypapophysis (broken in MDJ R-006, 0026, and 027). The centrum is delimited by subcentral ridges that are well defined anteriorly but vanish in the posterior half of the centrum.

Discussion: The Crotalus durissus complex (Neotropical rattlesnakes) occurs in dry areas from Mexico to northern Argentina, but is absent from Central American and Amazonian rainforests, resulting in a highly disjunctive distribution (Wüster et al., 2005). The Brazilian Crotalus durissus complex is represented by a single species, Crotalus durissus, which has a large geographical distribution among the central region of Cerrado, semi-arid and arid environments of northern region, savannas and open areas.

Figure 5. cf. Epicrates sp., incomplete midtrunk vertebra, MDJ R-020:A, dorsal view; B, ventral view. Scale bar = 5 mm.
of southern, southeastern and northern regions of Brazil (Melgarejo, 2003). The great distribution of C. durissus in Brazil is represented by the presence of five geographical forms, C. d. terrificus, C. d. cascavella, C. d. collineatus, C. d. ruruima, and C. d. marajoensis. All vertebrae described here share the only vertebral synapomorphy recognized for the Viperidae family: a well-developed and strongly anteroventrally oriented parapophyseal process (Zaher, 1999). However, the distinction among the Brazilian species on osteological features still requires further studies. At present, the vertebrae described here are similar to those of Crotalus durissus in the anterior edge of zygosphene concave, great anteroposterior extent of the neural spine, spatulate parapophyseal process, and presence of small paracotylar foramina. All of these subtle characters can distinguish Crotalus durissus from species of Bothrops, another genus with broad geographical distribution that occurs in most open areas in both northern and southern regions of Brazil.

**CONCLUDING REMARKS**

The new squamate assemblage from the late Quaternary Província Espeleológica de Ubajara described here comprises the lizard families Tropiduridae (Tropidurus sp.) and Teiidae (Ameiva sp.), and the snake families Boidae (cf. Epicrates sp.) and Viperidae (cf. Crotalus durissus), in addition to undetermined “colubrid” snakes reported by Hsiou et al. (2009). Unfortunately, all specimens are very fragmentary, and specific assignment is not possible. Camolez and Zaher (2010) reported some squamate assemblages from several regions of Brazil, but this work constitutes the first formally described record from the state of Ceará. Hence, the taxa reported in this paper contribute to a better understanding of the Brazilian Quaternary squamate fauna as a whole. Most of the previous records from northeastern Brazil were made based on uninformative reports, lacking a formal description, and their taxonomic validity is still unclear (Paula-Couto, 1980; Guérin, 1991; Guérin et al., 1993; Faure et al., 1999). For this reason, the present paper contributes to a major taxonomic refinement of the squamate faunas during the late Quaternary of northeastern Brazil. All material described here comes from levels with dating around 8,000 years BP, corresponding to the early Holocene. According to Oliveira et al. (in press) the age is consistent with the vertebrate fauna, because representatives of the Pleistocene South American megafauna have not been found in these levels. Like the tayassuids, marsupials, xenarthrans, and caviomorphs from these levels, the squamates do not indicate faunistic alteration during the early Holocene in comparison with the current fauna (Oliveira, 2010: Oliveira et al., in press). The paleoecological data indicated by the taxa reported are in accordance with the mosaic composition of the current environments of the Ubajara region, having humid forest in higher altitudes and open and dryer areas in the plains (Oliveira et al., in press).

**ACKNOWLEDGEMENTS**

We thank Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) for financial support of the project “Estudo Paleontológico dos Mamíferos das Cavernas do Parque Nacional de Ubajara, Ceará” (Universal/n° 473952/2008-4) headed by A.M. Ribeiro (MNC/FZBRS). Thanks also to A.M. Ribeiro (MCN/FZBRS), G. Lessa (UFV), and S. Teixeira (MUPHI) for help and camaraderie during fieldwork in July 2009; to Fundação Cearense de Apoio à Pesquisa e ao Desenvolvimento Científico e Tecnológico (FUNCAP, BPI 0341-1.07/08), and especially to Museu Dom José (MDJ) for the loan
of the specimens. A.S. Hsiou also thanks to CNPq in the form of Postdoctoral Fellowship (nº. 150803/2010-9); and P.V. Oliveira thanks Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) and CNPq for Master and Doctoral Fellowships developed at Programa de Pós-Graduação em Geociências at UFRGS and UFPE, respectively. We also thank to the three anonymous referees for their careful reviews and helpful suggestions.
