(Received 17 July 2012; published 26 October 2012)

The transport properties of the two-dimensional system in HgTe-based quantum wells containing simultaneously electrons and holes of low densities are examined. The Hall resistance, as a function of perpendicular magnetic field, reveals an unconventional behavior, different from the classical N-shaped dependence typical for bipolar systems with electron-hole asymmetry. The quantum features of magnetotransport are explained by means of numerical calculation of the Landau level spectrum based on the Kane Hamiltonian. The origin of the quantum Hall plateau $\sigma_{xy} = 0$ near the charge neutrality point is attributed to special features of Landau quantization in our system.

I. INTRODUCTION

The renewed interest to the study of the integer quantum Hall effect (QHE) has been manifested recently in investigation of the anomalous QHE state in graphene, which provides electron or hole excitations near the Dirac point of a double-cone energy spectrum. It has been predicted and observed that quantized values of the Hall conductance $\sigma_{xy} = v e^2/h$ correspond to filling factors $\nu = 4(n + 1/2)$, where $n = 0, \pm 1, \pm 2, \ldots$ are integers and the factor of 4 accounts for double degeneracy in both spin and valley numbers. The half-integer form reflects a specific property of Landau quantization for massless Dirac fermions. In particular, zero Landau level, whose position coincides with the Dirac point, is composed from half hole and half electron states, so the Hall conductance indicates a smooth transition from holelike (positive $\nu$) to electronlike (negative $\nu$) behavior as the Fermi energy goes up through this point. In very strong magnetic fields the spin degeneracy (and, possibly, the valley degeneracy) is lifted, which means opening the gap at the Dirac point. Theoretical models considering electron transport in these conditions can be classified in two groups: quantum Hall metal (spin-first lifting scenario) and quantum Hall insulator (valley-first lifting scenario). In the spin-first scenario, there exists a pair of counterpropagating chiral edge states (with opposite spins) in the gap so that a quantized Hall state at $\nu = 0$ appears. These states provide a dominant contribution to the conductivity, while the bulk transport is suppressed by the energy gap. This leads to divergence of the longitudinal resistivity $\rho_{xx}$ and smooth zero crossing of the Hall resistivity $\rho_{xy}$. In the valley-first scenario, no edge states exist in the gap and the divergence of both $\rho_{xx}$ and $\rho_{xy}$ at $\nu = 0$ is expected.

Since an unconventional quantum Hall state at $\nu = 0$ does not rely on relativistic dispersion of excitation, which is a specific case of graphene, it can be realized in other materials where two-dimensional (2D) electrons and holes coexist. The wide CdHgTe/HgTe/CdHgTe quantum wells, where separation of the size-quantized subbands is relatively small, are of particular interest in this connection. The 2D conduction (c) band in such systems is formed from the first heavy-hole subband ($h_1$) whose effective mass is positive, while the second heavy-hole subband ($h_2$) forms the upper part of the 2D valence (v) band. Owing to a uniaxial strain of the HgTe layer, which is caused by the lattice mismatch of HgTe and CdTe or CdHgTe, the energy spectrum of the $h_2$ subband is essentially nonmonotonic and has maxima away from the Γ point of the 2D Brillouin zone. Depending on the well width, strain strength, and interface orientation, the band structure can be of the two following kinds: indirect-gap 2D semiconductor and 2D semimetal (Fig. 1), which differ, respectively, by the absence or presence of the overlap of $h_1$ and $h_2$ subbands. In both these cases, a variation of the Fermi energy may cause a transition between holelike ($\sigma_{xy} > 0$) and electronlike ($\sigma_{xy} < 0$) behavior, as is understandable even from a classical transport picture. Indeed, multiple intersections of the Fermi level with nonmonotonic energy spectrum (Fig. 1) lead to a complicated Fermi surface for 2D electrons (Fermi arc) composed of more than one closed branch providing both electronlike and holelike orbits in the presence of the perpendicular magnetic field.

Recently, it has been demonstrated that the Hall conductivity of CdHgTe/HgTe/CdHgTe quantum wells of 20 nm width and [013] interface direction exhibits a quantized plateau $\sigma_{xy} = 0$ in the magnetic fields of a few tesla when the gate voltage is varied in the vicinity of the charge neutrality point (CNP). The universality of the edge-state transport picture suggests the existence of a pair of counterpropagating edge states in such 2D systems, which is equivalent to QHE near the Dirac point in graphene within a spin-first scenario. Despite this similarity, one should point out several differences. Unlike the case of graphene, the observation of the QHE state with $\sigma_{xy} = 0$ in HgTe quantum wells does not require ultrahigh magnetic fields. More importantly, the band structure of HgTe quantum wells is very different from that of graphene. Graphene is a gapless 2D material with symmetric and monotonic energy spectrum of electrons and holes. The $n = 0$ Landau level resides precisely at the electron-hole symmetric
more than one branch. The straight lines show the point (Dirac point), which allows for a \( \sigma_{xy} = 0 \) QHE when the fourfold (spin and valley) degeneracy is lifted. In wide HgTe quantum wells the energy spectrum of the v-band is nonmonotonic, and the extrema of the c-band and v-band are shifted in momentum space with respect to each other. The simplest consequence of such asymmetry is that zero crossing of the Hall resistivity takes place away from the CNP, as shown below. The overlap of the c-band and v-band makes the transport picture even more complicated. The question about mechanisms leading to opening of the gap responsible for the \( \sigma_{xy} = 0 \) QHE in wide HgTe quantum wells requires further consideration.

In this paper, we present experimental results on the Hall resistivity in 20 nm wide HgTe-based quantum wells with [001] interface orientation containing simultaneously electrons and holes. The densities of carriers in these wells are considerably smaller those those for the [013]-, [112]-, and slightly wider [001]-grown wells examined previously in our experiments.\(^7\),\(^10\),\(^12\),\(^13\) For this reason, we see quantum features in transport at smaller magnetic fields. Apart from the existence of the \( \sigma_{xy} = 0 \) plateau in the dependence of Hall conductivity on the gate voltage, we have found an unusual nonmonotonic dependence of the Hall resistivity \( \rho_{xx} \) on the magnetic field. This dependence essentially differs from the classical N-shaped Hall resistivity expected for electron-hole systems.\(^7\),\(^10\) A theoretical consideration based on calculation of the Landau level spectrum for our structure qualitatively explains the main features of our observations and helps us to uncover a mechanism of transition to the \( \sigma_{xy} = 0 \) state in the systems under investigation.

The paper is organized as follows. In Sec. II we describe the details of the experiment and give experimental results. Section III presents a theoretical basis for consideration of magnetotransport in 2D semimetals, Landau level calculation for wide HgTe quantum wells, and discussion of the results. The conclusions are briefly stated in the final section.

II. EXPERIMENT

The Cd\(_{0.65}\)Hg\(_{0.35}\)Te/HgTe/Cd\(_{0.65}\)Hg\(_{0.35}\)Te quantum wells with [001] surface orientations and the width of 20 nm were prepared by molecular beam epitaxy. A detailed description of the sample structure has been given in Refs. 7, 12, and 13. The top view of a typical experimental sample is shown in the inset to Fig. 2(a). The sample consists of three 50 \( \mu \)m wide consecutive segments of different lengths (100, 250, and 100 \( \mu \)m), and eight voltage probes. The ohmic contacts to the 2D layer were formed by the in-burning of indium. To prepare the gate, a dielectric layer containing 100 nm SiO\(_2\) and 200 nm Si\(_3\)N\(_4\) was first grown on the structure using the plasmochemical method. Then the TiAu gate was deposited. The rate of the density variation with gate voltage is estimated as \( \alpha = 1.09 \times 10^{15} \text{m}^{-2} \text{·V}^{-1} \). The magnetotransport measurements in these structures were performed in the temperature range 0.8–10 K and in magnetic fields up to 5 T using a standard four-point circuit with a 3–13 Hz alternating current of 1–10 nA through the sample, which is sufficiently low to avoid the overheating effects. Several devices from the same wafer have been studied.

The longitudinal resistivity \( \rho_{xx} \) and corresponding Hall resistivity \( \rho_{yx} \) acquired by varying the gate voltage at a constant magnetic field \( B = 5 \text{T} \) are shown in Fig. 2(a). Figure 2(b) shows the longitudinal conductivity \( \sigma_{xx} \) and Hall conductivity \( \sigma_{yx} \) calculated from the experimentally measured resistivities by tensor inversion. Possible admixtures of longitudinal and Hall resistivities, caused by contact misalignment and inhomogeneities, were removed, by symmetrizing all measured values for positive and negative magnetic fields. We may see that calculating the conductivities from the magnetoresistance peak at the CNP and a zero crossing of the Hall resistance yields a very small longitudinal conductivity \( \sigma_{xx} \) and a quantized zero plateau in the Hall conductivity \( \sigma_{yx} \) at \( v = 0 \). This behavior,
observed in the fields above 3.5 T, agrees with our previous study of the quantum Hall effect near CNP in wide HgTe quantum wells in samples with [013] surface orientation.12

Now we turn our attention to magnetoresistance measured as a function of the gate voltage with increasing magnetic field, shown in Fig. 3. For higher voltages, corresponding to electronlike conductivity, all the quantized plateaux are already developed in the field of 1 T. In the field of 0.5 T, however, we see only a short plateau at \( \nu = -1 \) and a weak indication of \( \nu = -3 \) plateau. For lower voltages, corresponding to holelike conductivity, we do not see any well-developed plateaux up to 3 T, although above 1.5 T there is periodic flattening of the Hall resistance picture possibly suggesting that the effects of Landau quantization become important also for holes. Surprisingly, the peak of the resistivity and the smooth zero crossing point of the Hall resistivity, which has been identified previously with CNP, both are shifted to higher positive voltage with increasing \( B \). At weak magnetic fields this shift is linear in \( B \), while at higher fields a saturation is reached (no more shift occurs).

The most intriguing behavior is observed in the magnetic-field dependence of the Hall resistivity. In Figs. 4(a) and 4(b) we give detailed plots of \( \rho_{xx} \) and \( \rho_{yx} \) for different gate voltages near CNP. Instead of a smooth N-shaped dependence of the Hall resistivity suggested by a classical magnetotransport theory for semimetals (see Sec. III) and observed in our previous experiments, we see a nonmonotonic dependence showing a number of remarkable features discussed below. Up to the fields of 0.4 T, the Hall resistivity behaves nearly linear with \( B \), demonstrating, however, a weak shoulder identified as a quantized plateau \( \rho_{yx} = -h/2e^2 \). At \( B \approx 0.45 \) T we see a short plateau where the Hall resistivity almost reaches the resistance quantum \( \rho_{yx} \approx 0.92(-h/2e^2) \), which is accompanied by a deep minimum in \( \rho_{xx} \) in agreement with conventional quantum Hall behavior in a unipolar (n-type) system. With further increase in magnetic field (\( B > 0.5 \) T) the absolute value of the Hall resistivity drops down. In the interval 2 T < \( B < 3 \) T there appear new features resembling the plateaux with \( \rho_{yx} \) ranging from 0 to \( h/e^2 \) in the chosen interval of gate voltages. The plateau \( \rho_{yx} = h/e^2 \) corresponds to conventional quantum Hall effect in a hole (p-type) system, and is accompanied by a minimum in \( \rho_{xx} \). However, these Hall plateaux do not exhibit exact quantization, as is typical for the states not yet fully formed in the magnetic field. Moreover, the value of \( \rho_{xy} \) smoothly changes with the gate voltage, which possibly indicates that the Fermi level does not lie in the region of localized hole states between Landau levels and the contribution of bulk delocalized states to transport is essential. Finally, in the region above 3.5 T \( \rho_{yx} \) demonstrates a complicated nonmonotonic behavior which strongly depends on the gate voltage, while the resistivity \( \rho_{xx} \) starts to grow up sharply.

The observed features of Hall resistance and longitudinal resistivity are discussed in the next section using both classical and quantum approaches to magnetotransport in 2D semimetals.
III. THEORY AND DISCUSSION

The calculated energy spectrum of carriers in the quantum well investigated in our experiment is shown in Fig. 5. The calculations are based on a numerical solution of the eigenstate problem for the 6 × 6 matrix Kane Hamiltonian under approximation of a symmetric rectangular confining potential of the Cd_{0.65}Hg_{0.35}Te/HgTe/Cd_{0.65}Hg_{0.35}Te heterostructure. We used the following parameters. The conduction- and valence-band offsets of the heterostructure under investigation are $U_c = 0.84$ eV and $U_v = 0.36$ eV, respectively, the gap energy in HgTe is $\varepsilon_g = -0.3$ eV, and the spin-orbit splitting energy (both in HgTe and Cd_{0.65}Hg_{0.35}Te) is $\Delta = 1.0$ eV. The Kane matrix element $P$ and the Luttinger parameters $(\gamma_1, \gamma_2, \gamma_3)$ of HgTe and CdTe are listed in the table of Ref. 15. The main effect of the uniaxial strain of the HgTe layer was taken into account by introducing a shift $E_{st}$ of the light-hole energy with respect to the heavy-hole energy in the Hamiltonian. We use $E_{st} = 15$ meV, based on the quantity of $E_{st} = 22$ meV given in Ref. 9 for HgTe on a pure CdTe substrate. The calculations demonstrate that our system is a 2D semiconductor. Owing to a difference in the Luttinger parameters $\gamma_2$ and $\gamma_3$, the spectrum of the 2D v-band is anisotropic. This leads to formation of four v-band valleys along the directions [11], [1̅1], [1̅1], and [1̅1] in the plane of 2D momentum $p = (p_x, p_y)$, with extrema at $p/h \simeq 0.26$ nm$^{-1}$. The single c-band valley with minimum at $p = 0$ is almost perfectly isotropic. The corresponding five-branch Fermi arc is shown in the inset. With lowering Fermi level $\varepsilon_F$, the picture of the Fermi arc is modified. As $\varepsilon_F$ passes through the saddle points and, further, through the c-band minimum at $p = 0$, the Fermi arc becomes composed of, respectively, three and two branches encircling the point $p = 0$. Note that the spectrum of 2D states in our model is spin-degenerate, because the contributions to the Kane Hamiltonian due to bulk inversion asymmetry are neglected, and the quantum well is assumed to be symmetric, which corresponds to our experimental situation. In asymmetric quantum wells the 2D states become spin-split.

Some features observed in our experiment, as well as in the previous experiments on 2D semimetals (see Refs. 7, 10, and 13), can be understood from consideration of the classical magnetoresistance of the system with energy spectrum $\varepsilon_p$ of semimetallic type shown in Fig. 5. The expressions for electron and hole densities can be written as $n_e = 2S_e/(2\pi h)^2$ and $n_h = 2S_h/(2\pi h)^2$, where the factor of 2 accounts for spin degeneracy and the quantities $S_i$ ($i = e, h$) are given by the integrals over energy: $S_i = \int d\varepsilon s_i(\varepsilon)(-\partial f_\varepsilon/\partial \varepsilon)$. Here $f_\varepsilon$ is the Fermi-Dirac distribution function and $s_i(\varepsilon)$ is the area in the ($p_x, p_y$) plane encircled by the isoenergetic lines $\varepsilon = \varepsilon_0$ under the condition that the sign of the transverse component of the group velocity for these lines is either positive ($i = e$) or negative ($i = h$). At zero temperature, when $\partial f_\varepsilon/\partial \varepsilon = -\delta(\varepsilon - \varepsilon_F)$, $S_e$ and $S_h$ are the areas encircled by the Fermi arcs with positive and negative transverse group velocities, respectively. Using this representation of $n_e$ and $n_h$, it can be demonstrated that the linear Hall conductivity in the limit of classically strong magnetic field $B$, when scattering of the carriers during their cyclotron motion is neglected, is written as

$$\sigma_{xy} = -|e|(n_e - n_h)/B.$$

This expression is valid for arbitrary energy spectrum and suggests that the Hall conductivity changes its sign at CNP ($n_e = n_h$). However, at weaker $B$, when scattering is essential, the point of zero $\sigma_{xy}$ is shifted away from the CNP. Indeed, the Hall conductivity becomes sensitive not only to the signs but also to the absolute values of the group velocities along the branches of the Fermi arc, because these velocities determine the densities of states and scattering probabilities.

For arbitrary $B$, there is no exact solution of the kinetic equation describing the magnetotransport in semimetals with anisotropic energy spectra. However, both $\sigma_{xy}$ and $\sigma_{xx}$ can be written explicitly if the Fermi energy is close to the valence-band extrema so that the energy spectra everywhere in the vicinity of $\varepsilon_p = \varepsilon_F$ are approximated by parabolic functions. In this case, which corresponds to the picture given in the inset of Fig. 5, the components of the conductivity tensor at low temperature are the sums of contributions from two groups of carriers near the extrema of the conduction and valence bands (i.e., the electron and hole contributions):

$$\sigma_{xx} = \sigma_{xx}^{(e)} + \sigma_{xx}^{(h)}, \quad \sigma_{xy} = \sigma_{xy}^{(e)} + \sigma_{xy}^{(h)},$$

$$\sigma_{xx}^{(i)} = |e|n_iB/B^2 + \beta_i^2, \quad \sigma_{xy}^{(i)} = \mp |e|n_iB/B^2 + \beta_i^2,$$

where $\beta_i = m_i/|e|\tau_i$ are the inverse mobilities of electrons and holes expressed through the corresponding effective masses $m_i$ and scattering times $\tau_i$. The signs $- and +$ in $\sigma_{xx}^{(i)}$ stand for electrons and holes, respectively. The expressions (2) and (3) turn out to be analogous to known expressions for two-component electron-hole systems (see for example, Ref. 16).
The introduction of the effective mass \( m_e \) is natural, since the c-band spectrum is isotropic and parabolic in a wide energy range. The effective mass \( m_k \) is introduced as \( m_k = \sqrt{m_1 m_2} \), where \( m_1 \) and \( m_2 \) are the masses characterizing the v-band energy spectrum along the main axes of the ellipses. From our calculations (Fig. 5), we find \( m_e = 0.03 m_0 \) and \( m_h \approx 5 m_e \), so the density of hole states (taking into account fourfold valley degeneracy) is about 20 times greater than the density of electron states. This means that at low hole densities the Fermi energy is pinned near the valence band extremum, and the parabolic approximation for \( E_g \) in the valence band is justified.

The expressions (2) and (3) lead to the Hall resistivity in the form

\[
\rho_{xy} = \frac{B}{|e|} \left( \frac{n_e n_h - n_h n_e}{(n_e - n_h)^2 + \beta_e^2} \right) + \frac{(n_e \beta_e^2 - n_h \beta_e^2)}{(n_e - n_h)^2 + \beta_e^2}.
\]

(4)

Since \( m_h \gg m_e \) and, consequently, \( \beta_h \gg \beta_e \), the condition for zero \( \rho_{xy} \) at low \( B \) is realized at \( n_h > n_e \), away from the CNP. The gate voltage \( V^{(0)} \) corresponding to zero crossing can be found from Eq. (4) combined with the expression \( n_e - n_h = \alpha (V_g - V^{(CNP)}) \), where \( \alpha \) is a constant specified for our sample in the previous section. With increasing \( B \), the voltage \( V^{(0)} \) moves towards the CNP gate voltage \( V^{(CNP)} \), first linear with \( B \), then saturating in the close vicinity of the CNP. Thus the behavior of the zero crossing point shown in Fig. 3(b) follows from the classical expression (4). The same expression describes N-shaped magnetic-field dependence of the Hall resistance at fixed \( V_g \), under the condition that \( n_h > n_e \). However, the Hall resistance plotted in Fig. 4(b) is different from the simple N-shaped dependence and cannot be described within the classical theory.

To account for the quantum features of the magnetotransport in our system, it is important to get an idea of how the energy spectrum is quantized in the magnetic field. To calculate the Landau levels (LLs) of HgTe quantum wells, we have used isotropic approximation in the Kane Hamiltonian, when the Luttinger parameters \( \gamma_2 \) and \( \gamma_3 \) both are replaced by \( (\gamma_2 + \gamma_3)/2 \). In this approximation, the problem is greatly simplified, since the columnar eigenstates of the 6 \( \times \) 6 matrix Kane Hamiltonian become representable in the form (see Ref. 17 for \( 4 \times 4 \) Luttinger Hamiltonian)

\[
\left( u^1_n \phi_{n-2}, u^2_n \phi_{n-1}, u^3_n \phi_{n-3}, u^4_n \phi_{n-2}, u^5_n \phi_{n-1}, u^6_n \phi_n \right)^T,
\]

(5)

with the oscillatory functions \( \phi_n \) \((n \geq 0)\) satisfying the relations \( k_- \phi_n = \phi_{n-1} \sqrt{2n/\ell} \) and \( k_+ \phi_n = \phi_{n+1} \sqrt{2(n+1)/\ell} \), where \( \ell = \sqrt{\hbar/e B} \) is the magnetic length. The states are, therefore, described by the LL number \( n \), and for each \( n \) one can find numerically the set of the components \( u^m_n(z) \) \((m = 1, 2, \ldots , 6)\) and the corresponding discrete energies \( \epsilon_{jn} \), where the number \( j \) accounts for both subband number and spin state. These energies, for two chosen values of the magnetic field, are plotted in Fig. 6.18 We point out the most essential properties of the LL spectrum. There are two states for each subband with LL number \( n \geq 3 \); these states differ by projection of spin. For \( n = 0, 1, 2 \) there is only one spin state within each heavy-hole subband, because the third component of the wave function (5) (spin-up heavy-hole component) is missing for these particular LL numbers. The levels originating from the c-band rapidly go up with increasing \( B \), except the first level (denoted as LA), which slowly moves down with the rate approximately 0.25 meV/T. In contrast, the levels originating from the v-band form a dense set, especially near the band extremum, and are slowly shifted with increasing magnetic field. The v-band levels \( n = 1 \) and \( n = 2 \) (the latter is denoted as LB) are an exception, because they move up rather rapidly with increasing field.

Based on the LL spectrum calculation, one may propose the following explanation of the behavior of magnetoresistance shown in Fig. 4. The entire interval of the magnetic fields investigated is subdivided in three regions: weak, intermediate, and strong magnetic fields, see Fig. 7, which are discussed below.

In weak magnetic field region (up to 0.45 T), the v-band states are not quantized, while the c-band states become quantized with increasing field because of the small effective mass, \( m_e = 0.03 m_0 \), in this band. Since both electrons and holes are present in the system, a fixed gate voltage means that \( n_h - n_e \) is constant. At small differences \( n_h - n_e \), the Fermi level is pinned close to the v-band extremum, because of a large density of states in the v-band. The QHE observed in this region of fields is caused by the passage of the c-band LLs through the Fermi level. At \( B \approx 0.45 \) T only the lowest c-band LL (level LA) remains occupied. Based on this scenario, we estimate the energy of semimetallic overlap as 1.1 meV. Although this value is considerably smaller than the 3 meV overlap following from the numerical calculations (Fig. 5), we do not...
Fig. 6. Since these are the states with different spin numbers, v-band level LB, which demonstrates a special behavior, is shown. The c-band and v-band states are shown in different colors. The field (from up to down), are emphasized and discussed in the text. The regions, corresponding to weak, intermediate, and strong magnetic fields (from up to down), are emphasized and discussed in the text. The c-band and v-band states are shown in different colors. The v-band level LB, which demonstrates a special behavior, is shown separately. The energy is counted from the position of level LA at $B \to 0$.

We find this discrepancy surprising, because the calculation puts aside many unknown factors (such as deviation of the quantum well potential from a simple rectangular one, partial relaxation of the strain inside the HgTe layer, etc.) which may shift the quantization energies within several meV. In weaker fields, we observe a signature of a plateau at c-band filling factor 3 ($\nu = -3$) but do not observe any plateau at $\nu = -2$. This fact becomes understandable from our numerical calculation showing that two next to level LA c-band LLs are almost degenerate at low $B$; see empty circles in the left panel of Fig. 6. Since these are the states with different spin numbers, the nature of the degeneracy is described in terms of negligible spin splitting for low-lying c-band states in weak magnetic fields.

The absence of any sizable contribution of holes to transport at CNP means that both longitudinal and Hall conductivities of holes are much smaller than $e^2/h$. Though such small hole conductivities cannot be entirely described within the classical (Drude) theory, it is likely that the holes experience strong localization. With semimetallic overlap of 1.1 meV, the hole density at CNP is estimated as $n_h \approx 1.2 \times 10^{11}$ cm$^{-2}$. Since the density of states in v-band is large, the presence of disorder makes it possible that the majority of holes, at such small $n_h$, occupy the tail of the density of states below the mobility threshold.

In the intermediate region (from 0.45 to 3 T), a single c-band level LA is occupied. The electron density $n_e$ increases linearly with the magnetic field. The difference $n_h - n_e$ is fixed by the gate, the hole density $n_h$ increases as well, and the holes become active in transport, causing a positive contribution to the Hall conductivity, and, consequently, a positive deviation of the Hall resistivity from $-h/e^2$. The increase of hole density by the gate leads to a similar effect. The components of the conductivity tensor are described by Eq. (2) with constant electronic components $\sigma_{xx}^{(e)} = 0$ and $\sigma_{xy}^{(e)} = -e^2/h$ which can be treated also as a contribution of the chiral edge state originating from level LA to transport. Thus, the dependence of resistivity on magnetic field and gate voltage is determined by the hole components of the conductivity tensor. The absence of a detailed knowledge of hole conductivity in the intermediate magnetic field region does not allow us to describe the Hall resistivity quantitatively. Whereas the monotonic change of the Hall resistivity in the region below 1.7 T might be explained within a classical representation of $\sigma_{xx}^{(h)}$ and $\sigma_{xy}^{(h)}$, the flat (plateaulike) features at higher fields possibly suggest that Landau quantization of holes already starts and makes $\sigma_{xx}^{(h)}$ and $\sigma_{xy}^{(h)}$ nearly independent on $B$ at $B > 1.7$ T. The fact that the value of $\rho_{xy}$ still smoothly changes with the gate voltage everywhere in this region means that the hole LLs are not well resolved; indeed these LLs form a dense set according to our numerical calculations. The contribution of bulk delocalized hole states to transport is, therefore, essential, and increases proportional to the hole density controlled by the gate.

In the high magnetic field region (above 3 T), the behavior of Hall and longitudinal resistances is determined by another important factor, the influence of the v-band level LB, which rapidly goes up with increasing magnetic field. The reduction of the hole contribution to Hall resistivity occurs when this level passes the Fermi level. According to our calculations, level LB crosses the upper one of the other v-band LLs approximately at $B = 3.6$ T. As this has happened, level LB itself becomes the upper one in the v-band and accumulates the majority of hole density. The remaining fraction of hole density, equal to $n_h - n_e$, is much smaller than the capacity of a single LL (at $B = 4$ T the capacity of a single LL is about $10^{11}$ cm$^{-2}$). Therefore, the Fermi level resides in the region of localized states in the tail of the next v-band LL, as shown in the lowest panel of Fig. 7, and bulk contribution to conductivity is negligible. The transport is determined by a pair of counterpropagating chiral edge states originating from LLs LA and LB, so the Hall conductivity $\sigma_{xy}$ is expected to be zero. Since small variations of the gate voltage do not shift the Fermi level from the region of localized states, a plateau $\sigma_{xy} = 0$ appears in the gate-voltage dependence of $\sigma_{xy}$; see Fig. 2(b).

The fact that we observe such a plateau starting from 3.5 T is consistent with the calculated behavior of LLs and emphasizes the crucial role of the level LB in magnetotransport in wide (semimetallic) HgTe wells. The large longitudinal resistance seen in Figs. 2(a) and 4(a) in this region is caused by scattering between counterpropagating chiral edge states, which is enhanced in the magnetic field. Such large resistance is observed also in nonlocal magnetotransport measurements in similar samples, which provides an additional confirmation of the picture of counterpropagating chiral edge modes in high magnetic fields.

A description of the longitudinal and Hall resistivities in the regime of counterpropagating edge states requires a more detailed consideration, because in view of strong scattering between these edge modes the edge-state transport is suppressed and small bulk contribution to conductivity might be important as well. We apply the formalism developed in Ref. 4 to a system comprising two edge states of electron ($e$) and hole ($h$) kind and a continuum of bulk states. The scattering between the edge states and the scattering between bulk states and each of the edge states is characterized by mean free path.
Depending on parameters, $\rho_{yx}$ may behave in different ways, and can be positive or negative. Assuming, for example, that both $\sigma_{xy}^{(h)}$ and $\sigma_{xx}^{(h)}$ are exponentially small, one cannot say that their ratio is small as well, so both contributions in the square brackets of Eq. (7) remain essential. If, in addition, $\sigma_{xy}^{(h)}/\sigma_{xx}^{(h)} \ll (\gamma L_y)^{-1}$, one obtains a much simpler result, $\rho_{yx} = \mu h/2e^2$ with $\mu = (g_b - g_e)/(g_b + g_e)$. This expression shows that $\rho_{yx}$ is smaller than $h/2e^2$ and its sign is determined by the bulk-edge scattering. In experiment, we see a complicated, variable-sign behavior of $\rho_{yx}$ as function of $B$ in Fig. 4(b) in the region of high magnetic fields. Without knowing dependence of the parameters entering Eq. (7) on magnetic field and gate voltage, we cannot describe this behavior in detail. Nevertheless, when $\sigma_{xy}$ is calculated from the expressions (6) and (7) by tensor inversion, the large value of $\rho_{xx}$ guarantees that $\sigma_{xy} \ll e^2/h$ regardless of the behavior of $\rho_{yx}$. This result correlates with the existence of the zero-conductivity plateau demonstrated in Fig. 2(b).

### IV. CONCLUSIONS

The possibility to create gated HgTe wells of different widths opens the avenue for investigation of bipolar 2D semimetals where electron and hole densities can be varied in a wide range. In this paper, we have examined low-temperature magnetotransport in the system with a very small semimetallic overlap, about 1 meV, which provides densities of electrons and holes of the order $10^{10}$ cm$^{-2}$. We have demonstrated, both experimentally and theoretically, that such a system has rather interesting properties generally following from electron-hole asymmetry and special features of Landau quantization in HgTe wells. The low density of carriers assures manifestation of quantum effects already at $B < 0.5$ T. With increasing magnetic field $B$, there exist three distinct transport regimes, where dependence of longitudinal and Hall resistances on $B$ is determined, respectively, by electrons, holes, and a pair of counterpropagating edge states originating from conduction and valence bands. Some of the features observed, in particular, a $B$-dependent shift of the zero Hall resistance point away from the charge neutrality point, are explained within the classical transport picture. The quantum features of magnetotransport are in agreement with the calculated Landau level spectrum of our system. This calculation uncovers the origin of the quantum Hall plateau $\sigma_{xy} = 0$ near the charge neutrality point by demonstrating that a broad gap responsible for this quantum Hall state is formed because one of the valence-band Landau levels rapidly goes up with increasing $B$. Very likely, the same mechanism describes the $\sigma_{xy} = 0$ quantum Hall state observed previously in 2D semimetals with higher carrier densities.

18. Of course, the numbering of the LLs can be chosen in a different way within each subband and each spin subsystem. The numbering used in this paper is based solely on the fact that $n$ is the number of the oscillatory function in Eq. (5).
